Approximating a two-machine flow shop scheduling under discrete scenario uncertainty✩

Adam Kasperski, Adam Kurpisz, Paweł Zieliński

Abstract

This paper deals with the two machine permutation flow shop problem with uncertain data, whose deterministic counterpart is known to be polynomially solvable. In this paper, it is assumed that job processing times are uncertain and they are specified as a discrete scenario set. For this uncertainty representation, the min-max and min-max regret criteria are adopted. The min-max regret version of the problem is known to be weakly NP-hard even for two processing time scenarios. In this paper, it is shown that the min-max and min-max regret versions of the problem are strongly NP-hard even for two scenarios. Furthermore, the min-max version admits a polynomial time approximation scheme if the number of scenarios is constant and it is approximable with performance ratio of 2 and not $(4/3 - \epsilon)$-approximable for any $\epsilon > 0$ unless $P=NP$ if the number of scenarios is a part of the input. On the other hand, the min-max regret version is not at all approximable even for two scenarios.

1. Introduction

The permutation flow shop is one of the most important and most extensively studied scheduling problems. The classical result by Johnson [1] shows that the problem with two machines is polynomially solvable. However, the three-machine case becomes strongly NP-hard [2]. The parameters in the problem are job processing times, which in the classical deterministic case are assumed to be precisely known.

In the existing literature several methods of dealing with imprecise parameters have been proposed. One of the most extensively studied is a robust approach, where a scenario set containing all possible realizations of the parameters, called scenarios, is specified. No probability distribution in the scenario set is given. In order to choose a solution several robust criteria can be applied (see [3] for a survey). The simplest one is the min-max criterion, under which we choose a solution minimizing the largest cost over all scenarios. A less conservative criterion is the min-max regret, under which we choose a solution minimizing the largest deviation from optimum over all scenarios. Both criteria have a long tradition in decision making under uncertainty (see, e.g., [4]). In the last two decades they were applied to discrete optimization problems. An extensive description of the robust approach and some applications of this framework to several discrete optimization problems can be found in [5].

The scenario set can be specified in several ways. In the discrete scenario case, which is discussed in this paper, we simply list all the possible scenarios. We then distinguish the bounded case, where the number of scenarios is bounded by a constant and the unbounded case, where the number of scenarios is a part of the input. In the interval case, for each parameter a closed interval containing all its possible values is given. Then the scenario set is the Cartesian product of all these uncertainty intervals. Note that in this case the scenario set contains infinite number of scenarios. It turns out that both uncertainty representations may lead to problems having quite different computational properties (see [6, 7, 8, 9, 10] and a survey [11]).

In this paper we consider the two machine permutation flow shop problem with uncertain job processing times modeled by a discrete scenario set. This problem was investigated in [5] and [12], where it was shown that its min-max regret version with only two scenarios is weakly NP-hard. Then a branch and bound algorithm and simple heuristics for computing a solution were proposed. No additional results on this problem have been known up to
The min-max regret permutation flow shop problem with interval job processing times was discussed in [5, 12, 13]. In [13] an $O(m)$-algorithm for the min-max regret permutation flow shop problem with 2 jobs and $m$ machines was proposed. In [5, 12], a branch and bound method and some heuristics for the two-machine case were given. Let us point out that the computational complexity of the problem with interval processing times is still an unsolved open problem. Other examples of the min-max (regret) versions of the classical scheduling problems, with both interval and discrete scenario uncertainty representation, can be found in [14, 15, 16, 17, 18, 19, 20, 21].

Our results. In this paper we first discuss the case in which the scenario set contains only two scenarios. We show that even such a restricted min-max (regret) problem is strongly NP-hard. This result excludes the existence of a fully polynomial-time approximation scheme (FPTAS) for the bounded case, which is in contrast to the other min-max (regret) combinatorial optimization problems such as the shortest path or the minimum spanning tree, whose min-max (regret) versions for bounded scenario set admit FPTAS’s [22]. Furthermore, we prove that the min-max regret version of the problem is not approximable while the min-max version admits a polynomial-time approximation scheme (PTAS) when the number of scenarios is constant. We then consider the min-max version of the problem with unbounded scenario set. We show that in this case the problem is approximable within 2, but not approximable within $(4/3 - \epsilon)$ for any $\epsilon > 0$ unless $P=NP$. Hence, it does not admit a PTAS.

2. The problem formulation

We are given a set of jobs $J = \{1, \ldots, n\}$, which must be processed on each of the two machines $M_1$ and $M_2$. Each job $i \in J$ is processed first on machine $M_1$ for time $p_{i1}$ and then on machine $M_2$ for time $p_{i2}$. Each job completes its processing on machine $M_1$ before it starts processing on $M_2$. Moreover, each machine can execute at most one job at a time. A schedule is a permutation $\pi = (\pi(1), \ldots, \pi(n))$ of jobs and it represents an order in which the jobs are processed on both machines. We use $\Pi$ to denote the set of all the schedules. We denote by $\sigma_{ij}(\pi)$ and $C_{ij}(\pi)$ the starting time and the completion time of job $i$ on machine $M_j$ in schedule $\pi$, respectively. The goal is to find a schedule $\pi \in \Pi$ having the shortest makespan, i.e.
$C_{\text{max}}(\pi) = \max_{i \in J} C_{ij}(\pi)$. This problem is denoted as $F2||C_{\text{max}}$ in Graham’s notation (see, e.g., [23]) and is polynomially solvable by well known Johnson’s algorithm [1].

In this paper we consider the case in which the processing times of jobs are uncertain. We model the uncertainty by specifying a scenario set $\Gamma = \{S_1, \ldots, S_K\}$, containing all possible realizations of the processing times. A vector $S = (p_{11}^{S}, \ldots, p_{n1}^{S}, p_{12}^{S}, \ldots, p_{n2}^{S}) \in \Gamma$ is called a scenario and $p_{ij}^{S}$ is the processing time of job $i$ on machine $M_j$ under scenario $S$. Now $\sigma_{ij}^{S}(\pi)$ and $C_{ij}^{S}(\pi)$ are the starting time and the completion time of job $i$ on machine $M_j$ in schedule $\pi$ under a given scenario $S \in \Gamma$ and $C_{\text{max}}(\pi, S) = \max_{i \in J} C_{ij}^{S}(\pi)$ is the makespan of $\pi$ under $S$. Let $C_{\text{max}}^{*}(S) = \min_{\pi \in \Pi} C_{\text{max}}(\pi, S)$, so $C_{\text{max}}^{*}(S)$ is the makespan of an optimal schedule under scenario $S$.

In order to choose a solution, two optimization criteria, called the min-max and the min-max regret, can be adopted. In the Min-Max $F2||C_{\text{max}}$ problem, we seek a schedule minimizing the largest makespan over all scenarios. Thus, we would like to solve:

$$\min_{\pi \in \Pi} \max_{S \in \Gamma} C_{\text{max}}(\pi, S).$$

Let us define $Z(\pi) = \max_{S \in \Gamma} \{C_{\text{max}}(\pi, S) - C_{\text{max}}^{*}(S)\}$. The value of $Z(\pi)$ is called the maximal regret of a schedule $\pi$, i.e. the largest deviation from the optimum over all scenarios. In the Min-Max Regret $F2||C_{\text{max}}$ problem, we wish to find a schedule that minimizes the maximal regret, that is

$$\min_{\pi \in \Pi} Z(\pi).$$

The optimal solutions to the min-max and min-max regret versions of $F2||C_{\text{max}}$ are called an optimal min-max schedule and an optimal min-max regret schedule, respectively.

The aim of this paper is to investigate the complexity and approximability of both robust problems. Up to now, we only know that the min-max regret version of the problem with two scenarios is NP-hard [12]. The reduction shown in [12] proceeds from the partition problem, which is not strongly NP-complete. So, it is possible that the min-max (regret) problem with 2 scenarios (or any fixed number of scenarios) is solvable in pseudopolynomial time and even admits an FPTAS. In Section 3 we will show that this is not possible unless P=NP.
3. Hardness results

In this section, we study the complexity and hardness of approximation of Min-Max (Regret) $F_2||C_{\text{max}}$. We first consider the restricted bounded case in which the number of scenarios equals 2. We then investigate the unbounded case.

3.1. The bounded case

We prove the following result:

**Theorem 1.** Min-Max $F_2||C_{\text{max}}$ is strongly NP-hard if $\Gamma$ contains only two scenarios.

**Proof.** We show a reduction from the following 3-PARTITION problem, which is known to be strongly NP-complete [24]:

3-PARTITION: Input: Positive integers $q$, $B$ and a set of integers $A = \{a_1, \ldots, a_{3q}\}$ such that $\sum_{k=1}^{3q} a_k = qB$ and $B/4 < a_k < B/2$ for $k = 1, \ldots, 3q$.

Question: Is there a partition of $A$ into sets $A_1, \ldots, A_q$, such that $\sum_{a \in A_k} a = B$ for each $k = 1, \ldots, q$?

Given an instance of 3-PARTITION, we construct an instance of Min-Max $F_2||C_{\text{max}}$ with $4q+1$ jobs and two scenarios $\Gamma = \{S_1, S_2\}$. The job processing times under both scenarios are shown in Figure 1.

We prove that the answer to 3-PARTITION is “yes” if and only if there exists a schedule $\pi$ such that $\max_{S \in \Gamma} C_{\text{max}}(\pi, S) \leq (2q + 1)B$. 

![Figure 1: An instance of Min-Max $F_2||C_{\text{max}}$.](image-url)
Suppose that there is a partition $A_1, \ldots, A_q$ of $A$ such that $\sum_{a \in A_k} a = B$, for each $k = 1, \ldots, q$. In Figure 2, a partial schedule $\pi' = (3q + 1, \ldots, 4q + 1)$ consisting of $q + 1$ jobs is shown. The makespan of $\pi'$ under both scenarios $S_1, S_2$ is equal to $(2q+1)B$. Observe that there are exactly $q$ time intervals of length $B$ on $M_2$ under $S_1$ and on $M_1$ under $S_2$. We form schedule $\pi$ by inserting (in any order) 3 jobs corresponding to each set $A_k$ between two consecutive jobs $3q + k$ and $3q + k + 1$, $k = 1, \ldots, q$. Since the elements of each set $A_k$ sum up to $B$, the processing times of the jobs corresponding to the sets $A_k$ fill $q$ time intervals on $M_2$ under $S_1$ and $M_1$ under $S_2$. Thus, the resulting schedule $\pi$ has the makespan equal to $(2q+1)B$ under scenarios $S_1, S_2$ and $\max_{S \in \Gamma} C(\pi, S) \leq (2q+1)B$.

Assume that there exists a schedule $\pi$ such that $\max_{S \in \Gamma} C_{\text{max}}(\pi, S) \leq (2q+1)B$. It is easily seen that the makespans of $\pi$ under the two scenarios are equal to $(2q+1)B$. Furthermore, the jobs on $M_2$ under $S_1$ must be processed without any idle time, which follows from equality $\sum_{i \in J} P_{i2} = (2q+1)B$. Notice that we have exactly $qB$ free time on machine $M_2$ under $S_1$ and on machine $M_1$ under $S_2$ for scheduling the jobs $1, \ldots, 3q$. From the definition of scenarios $S_1$ and $S_2$ it follows that a free time interval on $M_2$ under $S_1$ must correspond to exactly the same free interval on $M_1$ under $S_2$ and vice versa (in particular, job $3q+1$ must be processed first and job $4q+1$ must be processed last). Otherwise we could not fill the free time intervals without increasing the makespan $(2q+1)B$ under $S_1$ or $S_2$. We thus conclude that the partial schedule $\pi'$ must have the form presented in Figure 2. Of course, the order of jobs $3q+2, \ldots, 4q$ can be arbitrary because they have the same processing times under both scenarios. Hence, the jobs placed in $q$ free time
intervals of length $B$ define a partition of $A$ into subsets $A_1, \ldots, A_q$ whose elements sum up to $B$. \hfill\Box

From Theorem 1, it follows that the MIN-MAX $F2||C_{\text{max}}$ problem does not admit an FPTAS even for two scenarios, unless P=NP. The following theorem strengthens the previous result obtained in [12], where MIN-MAX REGRET $F2||C_{\text{max}}$ has been proved to be weakly NP-hard:

**Theorem 2.** MIN-MAX REGRET $F2||C_{\text{max}}$ is strongly NP-hard and not at all approximable, even for two scenarios, unless P=NP.

**Proof.** The reduction from 3-Partition is the same as in the proof of Theorem 1. It is easy to verify that each schedule has a makespan with the length at least $(2q + 1)B$ under both scenarios. Furthermore, schedule $\pi' = (1, \ldots, 3q, 3q + 1, \ldots, 4q + 1)$ is such that $C_{\text{max}}(\pi', S_1) = C_{\text{max}}^*(S_1) = (2q + 1)B$ and schedule $\pi'' = (3q + 1, \ldots, 4q + 1, 1, \ldots, 3q)$ is such that $C_{\text{max}}(\pi'', S_2) = C_{\text{max}}^*(S_2) = (2q + 1)B$ and thus they are optimal under $S_1$ and $S_2$, respectively.

Assume that the answer for 3-Partition is “yes”. Then there exists a schedule $\pi$ such that $\max_{S \in \Gamma} C_{\text{max}}(\pi, S) = (2q + 1)B$ (see the proof of Theorem 1). According to the above remark, we have $Z(\pi) = \max \{C_{\text{max}}(\pi, S_1) - C_{\text{max}}^*(S_1), C_{\text{max}}(\pi, S_2) - C_{\text{max}}^*(S_2)\} = 0$. If the answer for 3-Partition is “no”, then every schedule $\pi$ is such that $\max_{S \in \Gamma} C_{\text{max}}(\pi, S) > (2q + 1)B$ and, consequently, its maximal regret $Z(\pi)$ is positive. So, the problem of asserting whether there exists a schedule $\pi$ such that $Z(\pi) = \max_{S \in \Gamma} \{C_{\text{max}}(\pi, S) - C_{\text{max}}^*(S)\} \leq 0$ is strongly NP-complete and thus MIN-MAX REGRET $F2||C_{\text{max}}$ is strongly NP-hard. Also, MIN-MAX REGRET $F2||C_{\text{max}}$ is not at all approximable, unless P=NP. Otherwise, any polynomial time approximation algorithm applied to the constructed instance would solve in polynomial time the 3-Partition problem. \hfill\Box

### 3.2. The unbounded case

We now consider the unbounded version of MIN-MAX $F2||C_{\text{max}}$. We prove the following result:

**Theorem 3.** For the unbounded case MIN-MAX $F2||C_{\text{max}}$ is not $(4/3 - \epsilon)$-approximable for any $\epsilon > 0$, unless P=NP.
We show a gap-introducing reduction from a special case of Nae 3-SAT. The Nae 3-SAT problem is known to be strongly NP-complete [24] and is defined as follows:

**Nae 3-SAT**: Input: A set $\mathcal{V} = \{x_1, \ldots, x_n\}$ of Boolean variables and a collection $\mathcal{C} = \{C_1, \ldots, C_m\}$ of clauses, where each clause in $\mathcal{C}$ has exactly three distinct literals.

Question: Is there a truth assignment for $\mathcal{V}$ such that each clause in $\mathcal{C}$ has at least one true literal and at least one false literal?

We can assume that for each variable $x_k \in \mathcal{V}$ both $x_k$ and $\overline{x}_k$ appear in $\mathcal{C}$. If not, then we add two new clauses $(x_k \lor \overline{x}_k \lor x'_k)$ and $(x_k \lor \overline{x}_k \lor x''_k)$, where $x'_k$ is a new Boolean variable. Clearly, this modification does not change the complexity of the problem.

Given an instance of Nae 3-SAT, we construct the corresponding instance of $\text{MIN-MAX } F2 || C_{\text{max}}$ as follows. We associate with each clause $C_k = (l_{1k} \lor l_{2k} \lor l_{3k})$ three clause jobs $J^{1}_k$, $J^{2}_k$, $J^{3}_k$ corresponding to three literals in $C_k, k = 1, \ldots, m$. We also add an additional job $J_{m+1}$. So, the number of jobs is $3m + 1$. Next, we form scenario set $\Gamma$.

We first create the **clause scenarios**. Namely, we associate with each clause $C_k, k = 1, \ldots, m$, two scenarios. Under the first scenario the jobs $J^{1}_k, J^{2}_k, J^{3}_k$ have processing times equal to 2 on $M_1$ and all the remaining
processing times of clause jobs are set to 0. The job $J_{m+1}$ has zero processing time on $M_1$ and its processing time on $M_2$ equals 2. The second scenario is symmetric, that is the jobs $J_k^1$, $J_k^2$, $J_k^3$ have processing times equal to 2 on $M_2$ and all the remaining processing times of the clause jobs are set to 0. The job $J_{m+1}$ has processing time equal to 2 on $M_1$ and zero processing time on $M_2$ (see Figure 3). In the next step we add the contradictory literal scenarios as follows. For each pair of jobs $J_u^v$ and $J_q^r$ which correspond to contradictory literals $l_v$ and $l_q$, we create two scenarios. Under the first scenario the processing times of $J_u^v$ and $J_q^r$ on $M_1$ are set to 3 and all the remaining processing times of the clause jobs are set to 0. The job $J_{m+1}$ has processing time equal to 2 on $M_1$ and zero processing time on $M_2$ (see Figure 3). Note that in the constructed instance each schedule has makespan of length at least 6 under each scenario, so $\max_{S \in \Gamma} C_{\max}(\pi, S) \geq 6$. The cardinality of $\Gamma$ is bounded by a polynomial in the size of NAE 3-SAT and thus the instance of MIN-MAX $F_2||C_{\max}$ can be constructed in a time bounded by a polynomial in the size of NAE 3-SAT.

If the answer to NAE 3-SAT is "yes", then basing on a satisfying truth assignment, one can construct a schedule $\pi$, in which all the jobs corresponding to true literals are executed before $J_{m+1}$ and all the jobs corresponding to false literals are executed after $J_{m+1}$ in $\pi$. Notice that the three jobs corresponding to the literals of the same clause are placed in $\pi$ as follows: either one of these jobs precedes $J_{m+1}$ and the remaining two jobs follow it or two of them precede $J_{m+1}$ and the remaining one job follows it. This is due to the fact that the assignment is true and each clause in $C$ under this assignment has at least one true literal and at least one false literal. An easy verification shows that $\max_{S \in \Gamma} C_{\max}(\pi, S) = 6$ (see Figure 4). In the example shown in Figure 3, a satisfying truth assignment is $x_1 = 1$, $x_2 = 1$, $x_3 = 1$ and a corresponding optimal schedule is $\pi = (J_1^1, J_2^1, J_3^1, J_4^1, J_1^2, J_1^2, J_2^2, J_3^2)$ with makespans of length 6 under each scenario.

On the other hand, if the answer is "no", then for all schedules $\pi$ at least two jobs corresponding to contradictory literals either precede the distinguished job $J_{m+1}$ or follow it, or for at least one clause all three jobs corresponding to this clause either precede $J_{m+1}$ or follow it (because all the
\begin{align*}
C_{\text{max}}(\pi, S_1) &= 6 \\
C_{\text{max}}(\pi, S_2) &= 6
\end{align*}

Figure 4: (a) The makespans of schedule \( \pi = (..., J^u_v, ..., J^v_{m+1}, ..., J^r_q, ...) \) under two contradictory literal scenarios \( S_1, S_2 \). (b) The makespans of schedule \( \pi = (..., J^1_k, ..., J^2_{m+1}, ..., J^3_3, ...) \) under two clause scenarios \( S_1, S_2 \). Schedule \( \pi = (..., J^1_k, ..., J^2_{m+1}, ..., J^3_3, ...) \) has the same makespans.

literals in this clause have the same value). So, \( \max_{S \in \Gamma} F(\pi, S) \geq 8 \) (see Figure 5).

This yields a gap of 4/3 and \text{Min-Max } F2||C_{\text{max}} for the unbounded case is not approximable within \((4/3 - \epsilon)\) for any \( \epsilon > 0 \) unless P=NP.

Theorem 3 implies that \text{Min-Max } F2||C_{\text{max}} for the unbounded case does not admit a PTAS, unless P=NP.

4. Approximating Min-Max \( F2||C_{\text{max}} \)

In this section, we investigate the approximation of \text{Min-Max } F2||C_{\text{max}}. We start by introducing some additional notation:

- \( C^{\text{rob}}_{\text{max}} = \min_{\pi \in \Pi} \max_{S \in \Gamma} C_{\text{max}}(\pi, S) \) is the value of an optimal min-max schedule,
- \( L^S_j = \sum_{i \in \mathcal{J}} p^S_{ij} \) is the total load of machine \( M_j \), \( j = 1, 2 \), under scenario \( S \in \Gamma \),
- \( L^S_{\text{max}} = \max \{ L^1_S, L^2_S \} \) stands for the maximum machine load in \( S \),
- \( L_{\text{max}} = \max_{S \in \Gamma} L^S_{\text{max}} \) denotes the maximum machine load over the set of scenarios,
Figure 5: (a) The makespans of schedule \( \pi = (\ldots, J_v, \ldots, J_r, \ldots, J_m, \ldots) \) under two contradictory literal scenarios \( S_1, S_2 \). Schedule \( \pi = (\ldots, J_v, \ldots, J_r, \ldots, J_m, \ldots) \) has makespans \( C_{\text{max}}(\pi, S_1) = 6 \) and \( C_{\text{max}}(\pi, S_2) = 8 \). (b) The makespans of schedule \( \pi = (\ldots, J_v, \ldots, J_r, \ldots, J_m, \ldots) \) under two clause scenarios \( S_1, S_2 \). Schedule \( \pi = (\ldots, J_v, \ldots, J_r, \ldots, J_m, \ldots) \) has makespans \( C_{\text{max}}(\pi, S_1) = 6 \) and \( C_{\text{max}}(\pi, S_2) = 8 \).

\end{array}
\end{align*}
\]
deterministic job shop problem with a fixed number of machines proposed in [25] (we also use some ideas from [26] and [27]). However, the details of our algorithm will be different. Let us fix $\epsilon \in (0, 1)$ and let $\alpha > 0$ be a fixed number fulfilling the following inequality

$$\epsilon^{[2/\epsilon]} \leq \alpha \leq \epsilon.$$  \hspace{1cm} (1)

The precise value of $\alpha$ will be specified later (in Step 2). A job $i \in J$ is big if $l^i_{\max} \geq \alpha L_{\max}$, small if $\alpha L_{\max} < l^i_{\max} < \alpha L_{\max}$ and tiny if $l^i_{\max} \leq \alpha L_{\max}$. Accordingly, we partition the set of jobs $J$ into the three disjoint sets: big jobs, small jobs and tiny jobs, denoted by $B$, $S$ and $T$, respectively. We will build our PTAS in three steps.

**Step 1.** Let $UB = 2L_{\max}$ be the upper bound on $C_{\text{rob}}^{\max}$. Define $\delta = \alpha L_{\max}$ and let us assign the time interval $[0, UB + 2\delta|B|]$ to machines $M_1$ and $M_2$ under each scenario $S \in \Gamma$. We will refer to the interval on $M_j$ under $S$ as $\langle M_j, S \rangle$. Each interval $\langle M_j, S \rangle$ is partitioned into $UB/\delta + 2|B|$ intervals of the same length equal to $\delta$ and these intervals will be called the intervals of the first type. Consider a permutation $\pi$ of the big jobs. We place each big job $i \in B$ in each $\langle M_j, S \rangle$ so that $i$ starts at the beginning of some interval of the first type and the order of the big jobs in all $\langle M_j, S \rangle$ is the same as in $\pi$. Following the notation of [27], the resulting partial schedule will be called an outline and we will denote it by $O$ (our outline is, however, different than that in [27]). An outline is feasible if under any scenario: the jobs do not overlap on any machine, the precedence constraints between the jobs on machines $M_1$ and $M_2$ are not violated, and no job is completed after $UB + 2\delta|B|$. A sample feasible outline is shown in Figure 6. This outline corresponds to the permutation of big jobs $\pi = (1, 2, \ldots, |B|)$. Notice that many feasible outlines may correspond to the permutation $\pi$, but the number of all such outlines is finite and we can easily enumerate all of them. Now the key observation is that we can generate all the feasible outlines corresponding to all the permutations of big jobs in constant time, provided that the number of scenarios $K$ is constant. This follows from the fact that the number of big jobs, $|B|$, is bounded by $K \cdot UB/(\alpha L_{\max}) = 2K/\alpha$ and the number of intervals of the first type is bounded by $2/\alpha + 4K/\alpha$. Therefore, the number of all possible allocations of the big jobs to the beginning of intervals of the first type depends only on $K$, $\epsilon$ and $\alpha$ which are constant.
Step 2. Consider now the small jobs. The parameter $\alpha$ can be chosen so that the following inequality holds:

$$\sum_{i \in S} l_{i}^{\text{max}} \leq \epsilon K L_{\text{max}}.$$  \hfill (2)

The reasoning is similar to that in [28, 25]. Consider a sequence of real numbers $(\alpha_1, \alpha_2, \ldots, \alpha_{\lceil 2/\epsilon \rceil})$, where $\alpha_k = \epsilon^k$. Each $\alpha_k$ defines a set of small jobs $S_k = \{i \in J \mid \alpha_k \epsilon L_{\text{max}} < l_{i}^{\text{max}} < \alpha_k L_{\text{max}}\}$. Clearly $\mathcal{S}_j \cap \mathcal{S}_k = \emptyset$ for $j \neq k$. If the inequality (2) would be violated for all $S_k, k = 1, \ldots, \lceil 2/\epsilon \rceil$, then

$$\sum_{i \in J} \sum_{S \in \Gamma} (p_{i}^{S} + p_{i}^{S}) \geq \sum_{i \in S} \max(S) (p_{i}^{S} + p_{i}^{S}) = \sum_{i \in S} l_{i}^{\text{max}} \geq \sum_{k=1}^{\lceil 2/\epsilon \rceil} \sum_{i \in S_k} l_{i}^{\text{max}} > 2K L_{\text{max}},$$

which is a contradiction. Hence, inequality (2) must hold for at least one $S_k$ and we can fix $\alpha = \alpha_k$. Inequality (2) shows that the total length of the small jobs is upper bounded by $\epsilon K L_{\text{max}}$ and the total contribution of them to the makespan is at most $\epsilon K L_{\text{max}}$. Thus, we can simply append the small jobs at the end of the schedule constructed below.

Step 3. In the third and most involved step we add to each feasible outline $\mathcal{O}$ all the tiny jobs from the set $\mathcal{T}$. Let us number the big jobs with respect to their positions in $\mathcal{O}$, i.e. the first big job is indexed by 1 and the last one by $|\mathcal{B}|$. We denote by $\sigma_{kj}^{S}(\mathcal{O})$ and $C_{kj}^{S}(\mathcal{O})$ the starting and completion time, respectively, of the big job $k$ on machine $M_j$ under scenario $S$. For ease of notation, we will also define $C_{0j}^{S}(\mathcal{O}) = 0$ and $\sigma_{|\mathcal{B}|+1}^{S}(\mathcal{O}) = UB + 2|\mathcal{B}|\delta$ for each $S$ and $j = 1, 2$. Making use of these starting and completion times we create in each $(M_j, S)$ additional intervals $[C_{k-1j}^{S}(\mathcal{O}), C_{kj}^{S}(\mathcal{O})]$ indexed by $k = 1, \ldots, |\mathcal{B}|+1$, called the intervals of the second type. One sample interval

Figure 6: A sample outline for two scenarios corresponding to the sequence of big jobs $(1, 2, \ldots, |\mathcal{B}|)$. One sample interval of the second type indexed by 2 is also shown.
of the second type, labeled by 2, is shown in Figure 6. The time contained in an interval of the second type in \( \langle M_j, S \rangle \) will be used for processing tiny jobs in this interval on machine \( M_j \) under \( S \). In order to determine an assignment of the tiny jobs from \( \mathcal{T} \) to the intervals of the second type, corresponding to the outline \( \mathcal{O} \), we use a linear programming formulation. We define the following decision variables: \( x_{ik}, i \in \mathcal{T}, k = 1, \ldots, |\mathcal{B}| + 1 \) and \( C \), where \( x_{ik} = f, 0 \leq f \leq 1 \), means that the same fraction \( f \) of a tiny job \( i \) is processed in the interval \( k \) of the second type on each machine under each scenario and the value of \( C \) is the maximal length of an assignment (a schedule) of the big and tiny jobs over all scenarios. The linear programming formulation is the following:

\[
C_{\text{min}}(\mathcal{O}) = \min_{k=1}^{\mid|\mathcal{B}|+1} \sum_{i \in \mathcal{T}} x_{ik} = 1, \quad i \in \mathcal{T}, \quad (4)
\]

\[
C_{S}^{k-1,j}(\mathcal{O}) + \sum_{i \in \mathcal{T}} p_{ij}^{S} x_{ik} \leq s_{kj}^{S}(\mathcal{O}), \quad k = 1, \ldots, |\mathcal{B}|, \quad (5)
\]

\[
C_{S}^{j}(\mathcal{O}) + \sum_{i \in \mathcal{T}} p_{ij}^{S} x_{i|\mathcal{B}|+1} \leq C, \quad j = 1, 2, \quad S \in \Gamma, \quad (6)
\]

\[
C \leq UB + 2|\mathcal{B}||\delta|, \quad (7)
\]

\[
C, x_{ik} \geq 0, \quad i \in \mathcal{T}, \quad k = 1, \ldots, |\mathcal{B}| + 1. \quad (8)
\]

Constraints (4) assure that each tiny job \( i \) is fully assigned. Constraints (5) and (6) assure that the total sums of the processing times of tiny jobs assigned to the intervals of the second type do not exceed the lengths of these intervals. Constraints (6) together with the objective function minimize the maximal length, over all scenarios, of the assignment computed. Constraint (7) assures that this length is not too large, i.e. it does not exceed \( UB + 2|\mathcal{B}||\delta| \). It is not clear that the linear program (3)-(8) is feasible. We will provide a feasible solution for (3)-(8) in the following observation.

**Observation 2.** There is a feasible outline \( \mathcal{O}^* \) such that

\[
C_{\text{min}}(\mathcal{O}^*) \leq C_{\text{rob}}^{\text{max}} + 2|\mathcal{B}||\delta|. \quad (9)
\]

**Proof.** Let \( \pi^* \) be an optimal min-max schedule with the value \( C_{\text{rob}}^{\text{max}} \). We transform \( \pi^* \) into \( \tilde{\pi}^* \) using the method which is illustrated in Figure 7. Consider intervals \( \langle M_1, S \rangle \) and \( \langle M_2, S \rangle \) for some scenario \( S \). In Figure 7, the first
big job 1 is placed properly (i.e. at the beginning of some interval of the first type) on $M_1$ but not properly on $M_2$. So, we delay the starting times of all the jobs on $M_2$ by $a$, so that job 1 starts processing at time $\delta$ on $M_2$. The next big job is 2. It is not placed properly on $M_1$, so we delay the starting times of 2 and all the jobs succeeding 2 on $M_1$ and $M_2$ by $b$. Then job 2 is still not placed properly on $M_2$, so we delay the starting times of 2 and all the jobs succeeding 2 by $c$ on $M_2$. It is easy to see that delaying the starting times of these two big jobs increases the makespan under $S$ by at most $4\delta$.

We proceed in this way for all the subsequent big jobs and, as the result, we get the schedule $\tilde{\pi}^*$ in which all the big jobs start processing at the beginning of some intervals of the first type and the makespan under $S$ increases by at most $2\delta |B|$.

We can repeat this independently for each scenario $S \in \Gamma$ and the makespan of the resulting schedule $\tilde{\pi}^*$ increases under each scenario by at most $2\delta |B|$. Now, if we remove all the small and tiny jobs from $\tilde{\pi}^*$, then we obtain a feasible outline $O^*$ with the corresponding intervals of the second type. Observe that in $\tilde{\pi}^*$ each tiny job is fully assigned to some interval of the second type with respect to $O^*$. Consider the set of constraints (4)-(8) built with respect to $O^*$. Let us fix $C = C_{\text{rob max}} + 2\delta |B|$. Note that $C_{\text{max}} \leq UB = 2L_{\text{max}}$ and $C \leq UB + 2\delta |B|$. Making use of the starting times of the tiny jobs in $\tilde{\pi}^*$, we accommodate them in the intervals of the second type in $O^*$ and set $x_{ik} = 1$ if and only if job $i \in T$ is located in the $k$-th interval of the second type, $k = 1, \ldots, |B| + 1$. It is easily seen that the binary assignment to variables $x_{ik}$ satisfies all the constraints (4)-(8). In consequence, there is at least one feasible solution for $C = C_{\text{max}} + 2\delta |B|$, which implies (9).

We now make an observation on basic feasible solutions of the linear program (3)-(8).
Observation 3. In an optimal solution to the linear program (3)-(8) at most $2K(|B| + 1) + 1$ tiny jobs receive fractional assignment.

Proof. The linear program has $|T| + 2K(|B| + 1) + 1$ constraints and $|T|(|B| + 1) + 1$ variables. Thus a basic feasible solution has at most $|T| + 2K(|B| + 1) + 1$ positive variables. Let $T_1$ and $T_2$ be the sets of tiny jobs that receive a unique assignment and a fractional assignment in this solution, respectively. Hence, and from the fact that each job has at least one positive variable associated to it, which is due to (4), we have:

$$|T_1| + |T_2| = |T|,$$

$$|T_1| + 2|T_2| \leq |T| + 2K(|B| + 1) + 1.$$ 

Combining these inequalities yields $|T_2| \leq 2K(|B| + 1) + 1$. □

Observation 3 implies the tiny jobs $T_2$, receiving fractional assignment, are such that:

$$\sum_{i \in T_2} l_{max}^{i} \leq \left(2K(|B| + 1) + 1\right) \alpha \epsilon L_{max}.$$  \hspace{1cm} (10)

We will treat the jobs from $T_2$ similarly to the small jobs and append them at the end of the schedule constructed.

Now let us focus on the remaining tiny jobs $T_1$ that receive an integral assignment to the intervals of the second type in an optimal solution to (3)-(8). Notice that this assignment says nothing about the order of the tiny jobs within the intervals of the second type. Hence, we must establish a permutation schedule for the tiny jobs in each interval of the second type. In order to do this we use Sevastianov’s algorithm [29] for the Compact Vector Summation problem. We recall the following result on this problem:

Lemma 1 ([29, 30]). Consider a set of vectors $v_1, \ldots, v_n \in \mathbb{R}^d$ such that $\sum_{k=1}^{n} v_k = 0$. Then it is possible to find, in polynomial time (in $O(n^2d^2)$ time), a permutation $\varphi$ of $1, \ldots, n$ such that, for all $i = 1, \ldots, n$,

$$\left\| \sum_{k=1}^{i} v_{\varphi(k)} \right\|_{\infty} \leq d \max_{1 \leq k \leq n} \left\| v_k \right\|_{\infty}.$$
We now prove the following lemma that will be used to construct a permutation schedule of the tiny jobs $T_1$ in each interval of the second type. Later $p_{\text{max}}$ will be replaced by $p_{\text{max}}^T$, where $p_{\text{max}}^T$ is the maximal processing time among all the processing times of the tiny jobs.

**Lemma 2.** For any instance of the Min-Max $F2||C_{\text{max}}$ problem, there is an $O(n^2K^2)$-time algorithm which outputs a permutation schedule $\varrho \in \Pi$ such that

$$C_{\text{max}}(\varrho, S) \leq L_{\text{max}}^S + (K + 1)p_{\text{max}} \quad \text{for all } S \in \Gamma.$$  

(11)

**Proof.** The proof is adapted from [30, Sect. 1.5.2], where the use of Sevastianov’s algorithm to produce an algorithm for $F||C_{\text{max}}$ was presented. We first transform the instance of the problem so that the loads of the two machines under each scenario $S$ are equal, i.e. $L_{\text{max}}^S = L_1^S = L_2^S$. We do this by increasing the processing times of jobs of the less loaded machine, stopping the increase of a processing time as soon as it reaches $p_{\text{max}}$, until both machines are equally loaded. It is clear that if there is a permutation schedule $\rho$ satisfying (11) for the modified instance, then $\rho$ also satisfies (11) for the original one. The following equality holds for any permutation schedule $\pi$:

$$C_{\text{max}}(\pi, S) = I_2^S + \sum_{i=1}^n p_{\pi(i)}^{S(i)} = I_2^S + L_2^S \quad \text{for all } S \in \Gamma,$$  

(12)

where $I_2^S$ is the total idle time on machine $M_2$ under scenario $S$ in $\pi$. The amount of the idle time on machine $M_2$ under scenario $S$, before it starts processing job $\pi(i)$ can be determined by the following formula:

$$I_{\pi(i)}^{S} = \begin{cases} p_{\pi(1)}^S & \text{if } i = 1, \\ I_{\pi(i-1)}^{S} - \sum_{k=1}^{i-1} p_{\pi(k)}^S & \text{if } C_{\pi(i)}^{S(i)}(\pi) = C_{\pi(i-1)}^{S(i)}(\pi) + p_{\pi(i)}^S, \\ \sum_{k=1}^{i} p_{\pi(k)}^S & \text{if } C_{\pi(i)}^{S(i)}(\pi) = C_{\pi(i)}^{S(i)}(\pi) + p_{\pi(i)}^S. \end{cases}$$  

(13)

We can rewrite the third case of (13) as $p_{\pi(i)}^S + \sum_{k=1}^{i} (p_{\pi(k)}^S - p_{\varrho(k)}^S)$. Now, if we can find a permutation $\varrho$ such that

$$\sum_{k=1}^{i} (p_{\varrho(k)}^S - p_{\varrho(k)}^S) \leq Kp_{\text{max}}, \quad i = 1, \ldots, n, \quad \text{for all } S \in \Gamma$$  

(14)
then we conclude from (13) that $I_{g(1)}^S \leq \max\{I_{g(i-1)}^S, (K+1)p_{\text{max}}\}$ and, since $I_{g(1)}^S \leq p_{\text{max}}$, $I_2^S = I_{g(n)}^S \leq (K+1)p_{\text{max}}$. Because $\sum_{i=1}^n p_{g(i)}^S = L_2^S = L_{\text{max}}^S$, equality (12) implies (11).

It remains to show that a permutation $\rho$ fulfilling (14) can be constructed in $O(n^2K^2)$ time. In order to do this we apply Lemma 2. Let us define a set of $K$-dimensional vectors $\mathbf{v}_1, \ldots, \mathbf{v}_n$, where $\mathbf{v}_k = (p_{k1}^S - p_{k2}^S, p_{k1}^S - p_{k2}^S, \ldots, p_{k1}^S - p_{k2}^S)$, $k = 1, \ldots, n$. This set satisfies the assumptions of Lemma 1. Indeed, $\sum_{k=1}^n \mathbf{v}_k = (L_1^S - L_2^S, L_2^S - L_2^S, \ldots, L_1^S - L_2^S) = \mathbf{0}$ by equality $L_{\text{max}}^S = L_1^S = L_2^S$. Furthermore $\|\mathbf{v}_k\|_\infty \leq p_{\text{max}}$ for all $k$. Lemma 1 now shows that the required permutation $\rho$ can be determined in $O(n^2K^2)$ time.

Consider any interval of the second type, say the $k$-th. There is a subset of the tiny jobs $T_k$ assigned integrally to $k$ by the linear program. We construct a permutation schedule for these tiny jobs using the algorithm from Lemma 2. This algorithm produces a permutation schedule with the length under each scenario $S$ at most $\max\{\sigma_{k1}^S(\mathcal{O}) - C_{k-11}^S(\mathcal{O}), \sigma_{k2}^S(\mathcal{O}) - C_{k-12}^S(\mathcal{O})\} + (K+1)p_T^\tau$, see (11). Hence, in order to accommodate the tiny jobs according to the computed permutation schedule to the intervals $[C_{k-11}^S(\mathcal{O}), \sigma_{k1}^S(\mathcal{O})]$ and $[C_{k-12}^S(\mathcal{O}), \sigma_{k2}^S(\mathcal{O})]$, $C_{k-11}^S(\mathcal{O}) \leq C_{k-12}^S(\mathcal{O})$, $\sigma_{k1}^S(\mathcal{O}) \leq \sigma_{k2}^S(\mathcal{O})$, for all $S$ without violating its feasibility, it suffices to increase the length of the $k$-th interval of the second type on machine $M_2$ under each scenario $S$ by at most $(K+1)p_T^\tau$, i.e. we shift the big job $k$ and all the jobs starting after this big job to the right on machine $M_2$ under each scenario $S$ by at most $(K+1)p_{\text{max}}$.

We can apply the algorithm from Lemma 2 to each interval of the second type and the total increase of the length of the intervals of the second type is at most $(|\mathcal{B}| + 1)(K+1)p_T^\tau$.

We are now ready to provide our PTAS which works as follows. First, we generate all the feasible outlines. According to Observation 2, there must be a feasible outline $\mathcal{O}^*$ which satisfies inequality (9). The linear program applied to $\mathcal{O}^*$ gives us the partition of the set of the tiny jobs into $T_1$ and $T_2$. Then, we apply the algorithm from Lemma 2 to schedule the jobs from $T_1$ in each interval of the second type. Finally, we create any permutation schedule for $T_2 \cup S$ and append it to the end of the schedule constructed. As the result we get a permutation schedule for all the jobs in $\mathcal{J}$ with the maximal makespan over all scenarios $C_{\text{max}}^{\text{rob}}$. According to (9) and the construction described this makespan can be upper bounded as follows:

$$C_{\text{max}}^{\text{rob}} \leq C_{\text{max}}^{\text{rob}} + 2\delta|\mathcal{B}| + \sum_{i \in T_2} t_i^{\text{max}} + \sum_{i \in S} t_i^{\text{max}} + (|\mathcal{B}| + 1)(K+1)p_T^\tau.$$
Now using (1), (2), (10) and the conditions: \( \delta = \alpha \epsilon L_{\text{max}}, \ |B| \leq 2K/\alpha, \ C_{\text{max}}^{\text{rob}} \geq L_{\text{max}} \) and \( p_{T_{\text{max}}}^{T} \leq \alpha \epsilon L_{\text{max}}, \) we get after easy computations:

\[
\tilde{C}_{\text{max}}^{\text{rob}} \leq (1 + O(K^2)\epsilon)C_{\text{max}}^{\text{rob}}.
\]

For the constant values of \( K \) and \( \epsilon, \) our algorithm is polynomial with respect to the number of jobs \( n. \) Thus it is a PTAS for the problem considered.

5. Conclusions

In this paper we have investigated the two-machine flow shop problem under the discrete scenario uncertainty representation with bounded and unbounded scenario sets. For the bounded case, we have proved that the min-max version of the problem is strongly NP-hard even for two scenarios. This result excludes the existence of an FPTAS for the problem but admits the existence of a PTAS. In this paper, we have constructed a PTAS for the bounded min-max version of the problem. For the bounded min-max regret version we have shown that the situation is much worse, namely, in this case the problem has turned out to be strongly NP-hard and not at all approximable even for two scenarios. For the unbounded scenario set we have proved that the min-max version is approximable within 2 and not \((4/3 - \epsilon)\)-approximable for any \( \epsilon > 0. \) There is still an unresolved gap between the positive and negative approximation results for the unbounded case. The 2-approximation algorithm shown in this paper is trivial and further research should involve the development of efficient approximation algorithms with better than 2 worst case ratio for the unbounded min-max version of the problem.
